<u>Network Layer</u>

Lecture 15 Layer 3 Switching

How do we go from LAN to a much larger network? Why doesn't ethernet switching scale?

-> In the spanning tree, the path between two nodes could be long.

(potentially very unoptimal because we are not using all links)

→ The forwarding table, whose size can be as large as the number of hosts, can be very cumbersome to use.

This is a result of flat addressing.

To fix this, we use hierarchical addressing in IP.

→ If a switch in the tree goes down, we reconstruct the spanning tree.

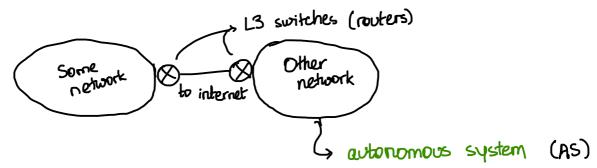

There are periodic "Hello" messages to ensure that the tree is intact.

(If not received by someone, we reconstruct)

In a large network this could happen often, thus wasting resources frequently.

→ Earlier, there were no common addressing scheme or communication protocols across the globe.

13 switches forward based on the IP address.

Each AS can choose its own internal routing protocol.

(the distance heuristic mentioned at the end of the prev. section)

There is intra-domain routing (within AS) and inter-domain nouting (between AS)

In the internet, inter-domain routing is done using BGP — the Border Gateway Protocol.

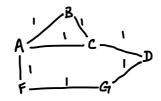

Let us start with intra-domain routing. It is broadly of two types: distance vector and link-state routing

They are essentially just algorithms to:

→ find shortest path (each hop is assigned a weight by the admin) avoid cycles.

A novter does not need to know the entire novte, only the next hop in a shortest path.

Distance vector routing uses a distributed version of the Bellman Ford algorithm.

A (and each node) first sends out (A, O)

Its IP - Litely

It then updates its forwarding table after hearing each message.

Destination	Next hop	Cod
A	-	D
В	B	1
C	С	ı
F	F	ı

Next, A sends its table to its own neighbours.

From C. it hears (C.D. (A.D. (B.1), (D.1)

			FROM	וי ג ט	r rugues	(C_1U) , (R_1)	J, (D, I), (را رسد
H	Hon	undatec	:ke	to Wa	ac.	Destination	Next hop	Cost
י ען	C. 67	then updates	10 Caple	ane	(L)	A	-	D
						В	B	ı
						C	С	ı
						F	F	ı
						D	C	2
						G	F	2

Proceeding, it builds up a forwarding table, choosing the neighbour closest to a destination at each step

What happens if a link fails?

A node X recognizes that the link has failed and sends this information to its neighbours, sowing that its distance to that node is now as.

Similarly, if a neighbour's next hop for that destination is X, it updates its own cost as as as well

This spreads until we reach a node with a different next hop.

If we receive a packet for that node in the intermittent period, it is discarded.

How often does this occur?

→ Triggered update: An event triggers a nouting update. (We try to send on a link and we full)

-> Periodic update: Periodically, give neighbours information about routing table.

No particular node knows the topology of the entire network.

Lecture 16 Count-to-Infinity and Link State Routing

The Distance Vector protocol essentially shares the dest and next columns of the routing table.

Let us look at the count-to-infinity problem.

Say

 $X \stackrel{1}{\longrightarrow} A \stackrel{1}{\longrightarrow} B$

Dest Next Cost Dest Next Cost

A A I X X I A A I
B A 2 B B I X A 2

Suppose the X-A link fails. Then A sends (X,∞) to B. Further, obt nearly the same time, suppose B sends (X,2) (to A)

(and (A,1))

A's table was

Dest Next Cost x - 00 and on hearing B, becomes x B 3

B B 1

and simultaneously, B's table becomes

Now, A tells B (X,3), (B,1) so B will update to (A,A,1), (X,A,4). This repeats ad infinitum, with the cost to X "counting to infinity".

One solution: Keep a maximum distance considered as ∞ and stop if we reach it. This value is 16 in RIP.

One other solution is split-horizon.

→ Do not advertise information about a destination to a neighbour if that neighbour is the next hop to the destination.

In our example, B would not tell A anything about X.

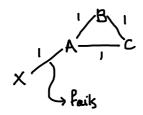

As a result, both nodes would end up \(\text{the (x,A,2) ending} \) with a (x, a) entity.

Another is split-horizon with Poisson reverse.

- A node tells its next hop to the destination that its distance to the destination is oo.

B sends advertisements (x,00) to A.

However, the above do not fix the problem in general.

there are also more general counterexamples that do not depend on this

A sends (x,00) to B and C Suppose the message to C is lost

Then, B's table is updated with (x, C, 3). Now, B tells this to A

(A is not its next hop anymore) and A's table is updated with (x, B, 4).

A will relay this to C. As before, this is a loop and the count-toinfinity problem arises once more.

In RIP (Routing Information Protocal),

The cost of all links is 1.

The routing problem is partially fixed ($16 \equiv \infty$ now) but as a result, we cannot have larger networks.

5 more than 16 hops

Distance Vector:

- + simple and easy to implement
- count-to-infinity and routing loops
- convergence of routing tables may take a long time.

The alternative is link-state routing.

Each node broadcasts information about costs to immediate neighbours. (sort of a flipped version of $D \cdot V \cdot -$ globally tell local information) instead of locally tell global information.

Each node can reconstruct the entire topology and find the shortest distance using any standard algorithm.

LSR uses Dijkstra's Algorithm, wherein each mode finds a shortest path tree to all the other nodes in the network.

A's routing table is then built from the tree.

Routing loops are not a problem because on link failure, the failure is broadcast to everyone (from both sides).

All nodes rerun Dijkstra's Algorithm.

- + No routing loops or count-to-infinity.
- + Convergence of routing table is fast.
- Algorithm is more complex (than Distance Vector)

The remaining question is: what do we choose for the costs?

We have studied how to use the weights to find the shortest paths. What should these be in practice?

A lower weight corresponds to being used more often

In ARPANET, there were 56 kbps and 9-6 kbps links. There were also terrestrial and satellite links.

Let us zoom in on a single link. What weight do we assign?

Idea 1. Use latency. The latency of a single packet on this link is equal to (queving delay + speed of light delay + transmission delay)

packet size
no. of lops

This latency keeps changing from packet to packet however. Take some time window instead and set the link weight as the average of all packets in the window.

The weight is low if

- -> the queve is relatively emply
- the link is fast

However, this encountered several problems.

→ Under heavy load, there were several routing oscillations. If we decide to use a link, the queue fills up and we switch back to another link.

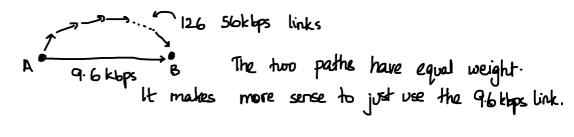

(Using a link increases its weight over time)

- · The end-to-end latency keeps changing, which might affect the application layer.
- The order in which packets are received might be wrong, since we
 could change link weights halfway through Again, this could affect
 application layer performance.
- Routing loops are possible because weights may change often. Lthe algorithm ensures acyclicity for fixed weights)

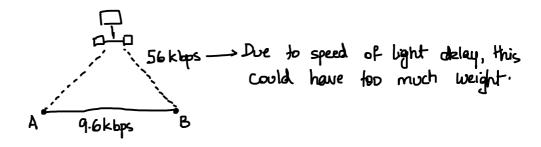

-> The range of link weights is large.

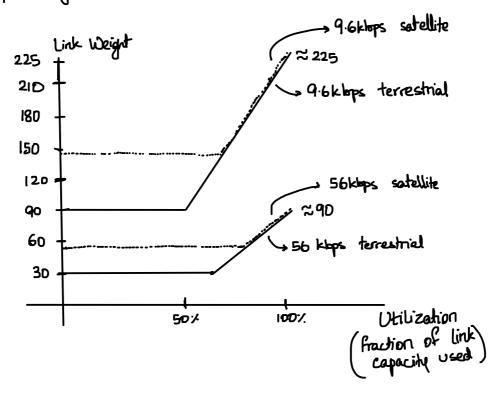

As a result, some links are penalized too much.

- Satellite links are penalized too much.

What they finally used is:

- → Retio of max wt. to min is ~7.
- → 56 kbps satellite preferred to 9.6 kbps terrestrial
- Weights charged infrequently.

What do we use today?

→ In OSPF,

link wt. = max
$$\left\{ 1, \frac{10^8}{\text{link speed (laps)}} \right\}$$
.

- In Network Operations Centers (NOCs), network engineers can manually change and set weights.

Lecture 18 | P Addressing

Recall that we have hard-coded MAC addresses in Layer 2.

The IP address (layer 3) is configurable.

IPv4 had 32 bits (not enough) - 1Pv6 has 128 bits.

NAT (Network Address Translation) is used to reuse IP addresses.

The IP address is written as

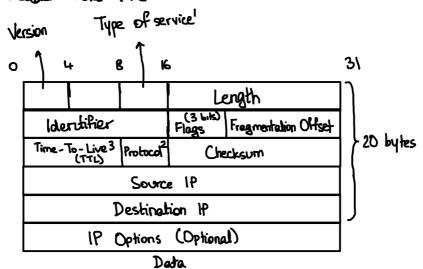

each 8 bits, written as decimal.

For example, an all 1s address is written as 255.255.255.255. Special addresses:

- · The all Is address is reserved for broadcast (to be read by all host machines).
- " 10. * . * . * or 192. * . * is a private IP address anything (They can be reused)

 Public IPs are usually unique on the internet.

The 1Pv4 header looks like

- 1. denorcate priority of packet
- 2 Protocol et next leyer
 - 6:TCP 17:UDP 1:ICMP
- 3. Packet survives iff TTL>0.

 Decremented at each router.

 Discard if TTL=0.

 (Fixes routing loops)

Let us now look at the IP addresses. We want the routing table to be small- (not size 232) Flat addressing like in Ethernet would be problematic. Say IP is a.b.c.d.

Assign a slice of addresses instead of arbitrary values. Keep some prefix, so now everyone's address in that region has a particular prefix, making it easier to store in the table.

Class B: 16 bits 16 bits Network Host

Class C: 24 bits 8 bits Network Host

Subnetting: Given a slice, how do we divide addresses among LANS and configure the internal router?

Say class C.

First, we should divide between the various LANs

A subject mask denotes which bits in the IP address to use when deciding which LAN to route to.

Say the subnet address for LAN 1 is S_1 and LAN 2 is S_2 . If the destination address is D, we check if

(D AND
$$M_1$$
) = S_1 or (D AND M_2) = S_2 (or neither)

The mark for LAN1

So if $13.52.30.*$, it

either LAN-
would be 1111.1111.0000.

(M could be equal to M2)

We may sometimes want to do the opposite. That is, combine multiple slices.

Can the entries at NI re

This process is called supernetting.

(Maybe the slices combine to form a single prefix)

An IP prefix is usually denoted as

a.b.c.d/N

Consider N leading bits Can the entries at R, be combined?

(Check if first N bits of destination correspond to that of a.b.c.d) For example, combine \Rightarrow = 128 112.128.0/24

$$|28.|12.|28 *$$

$$|28.|12.|28.*$$

$$|28.|12.|28.0 / 2|$$

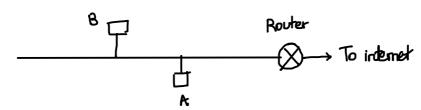

$$|28.|12.|28.0 / 2|$$

We should ensure that no addresses are missing in the middle.

This method using arbitrary prefix lengths is called CIDR - Classless Inter Domain Routing-

Lecture 19 ARP and DHCP

We now look at ARP-Address Resolution Protocol.

Suppose A wants to send a packet to B (and knows B's IP). What MAC layer frame does it send if it does not know B's MAC? (The ethernet frame has destination MAC after preamble)

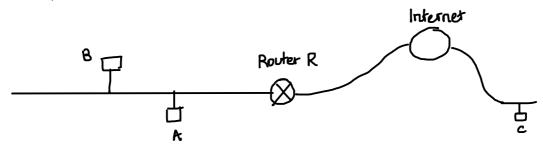

ARP helps us determine MAC given the IP. Is outside DLL, PHY.

A sends an ARP packet. (Preamble Dest. MAC | Source MAC | Type/Length | ARP packet | CRC)

- -> the destination MAC is all Is (broadcast)
- → the ARP packet contains the sender (A) MAC, sender 1P, target (B)

 MAC, and target 1P

 L> all Ds because it is unknown.
- -> Each receiver checks if their IP matches, and sends an ARP reply if it does.
- → The ARP reply has the sender (B) MAC, sender IP, target (A) MAC, and target IP. This is a unicoal frame.
- -> This information about B's MAC is stored in A's ARP cache. This has a timeout (of the order of minutes) because IP-MAC binding is not permanent we can switch out our WiFi card.

What do we do if C (instead of B) is problematic? It would be fixed if A manages to intelligently set the destination MAC as that of R if this is the case.

- (i) How does A know if the destination IP belongs to their own network?
- (ii) If not, how does it get R's MAC address?
- · For (i), we can AND the destination IP with the subnet mask and check if the resulting IP is equal to our own IP ANDED with the mask. (Dest-IP AND MASK == IP_A AND MASK) If it is, then B belongs to our own network.
- · For (ii), if we know R's IP address, we can perform usual ARP to get R's MAC.
 · How do we get R's IP short of manual configuration?
- If the 2 bytes assigned for the type/length are >1536, it corresponds to type.

 (not length)

In particular, 0 × 806 means that it is an ARP packet.

We get the default router's IPy using DHCP— Dynamic Host Configuration Protocol.

and our own IP

There should be a DHCP server on the network.

DHCP is above UDP, IP, DLL, PHY on the protocol stack.

(alongside application but shares information with 1P/DLL)

The data is broadcasted. The IP has a protocol field for UDP and a port number for DHCP.

L> 68, 67
L>DHCP client
DHCP sener

A sends out a DHCP "Discover" packet-

- The destination MAC is all Is. (broadcast)
- -> The destination IP is all Is. (broadcest)
- A receiver discards the packet if port 68 is not open.
- → The DHCP server replies with an offer, which contains a potential IP address for A (the server looks up its tables for a free address).

The destination MAC is A's.

The source MAC is the server's.

The source IP is the server's.

The destination IP is all 1s (broadcast) — A need not have configured itself with the correct IP address.

→ This is followed by a request from A for the IP address, and then the server acknowledges that the IP is assigned.

Why are we doing this in two rounds (discovery, offer, request, ack)?

- · There may be multiple servers, and we want to allocate a single IP.
- · When A receives the offer, it checks if this IP is already in use by sending out an ARP.

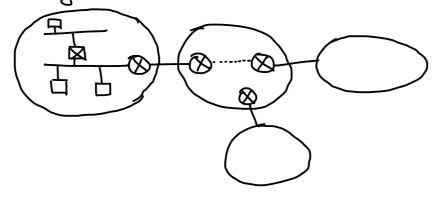

When we set the destination MAC as all Is, shouldn't it reach the entire internet? No, gateway routers do not send out IP broadcasts and keep them local to this network.

What if there are multiple networks with a single DHCP server? There is a relay agent that sends a unicast DHCP packet to the DHCP server, and forwards the offer to A after receiving it.

Now, we look at BGP (Border Gateway Protocol), which is used for inter-domain routing (routing between autonomous systems).

BGP

The As together form a network.

An autonomous system connected to multiple other AS' and paying them for their service is called a multi-homed customer

Autonomous systems with a wide coverage (across the country/globe) are called Tier 1 autonomous systems. They are usually not customers

An AS taking service directly from a tier 1 ISP is called a tier 2 Astier n tier (nti)

A customer is an AS that does not provide service to anyone

A peering link is a link between two AS', neither of which take service from the other (they co-operate and it is convenient to send through them). Their bandwidth is usually low to avoid misuse — they are under-provisioned since no-one gets paid for traffic on that link.

A service-level agreement gives a guarantee about the throughput/latency within a certain AS (NOT end-to-end). This is within the network, so depends on the link weights etc.

What does BGP do? It helps to hind a path across the AS-level graph-abstract the AS-level graph-abstract the AS-level graph-single nodes

There are BGP speakers, which communicate using the e-BGP protocol-external

They advertise the prefix/A.S. path/attributes as a BGP advertisement. To communicate between speakers of a single network, we use i-BGP.

The known prefix/As path/attributes are sent. interior

The path gets longer as we proceed.

(note that path is stored, not next hop)

So if an announcement with a certain address is made, we are guaranteeing that we can reach that address.

On peering links though, we might want to keep certain paths secret.

Corporate greed is a feature of BGP!

Even customers might not want to tell what it is connected to, for fear of being used as an intermediate service provider by the connected providers. BGP allows this too. It does not compel anyone to give out all their information.

Since there may be multiple paths to the same prefix, we must make a choice.

The communicating e-BGP routers are usually directly connected.

(e-BGP uses port 179) 80 for HTTP

In i-BGP, the learnt information is shared within the ASy to all the BGP speakers.

Using IGP

IGP is Interior Gateway Protocol, which is just normal intra-domain routing.

- → e-BGP speakers learn AS paths from neighbouring e-BGP routers in other AS'.
- → e-BGP nodes share learned information via i-BGP to other speakers in their As.
- BGP speakers select routes to various IP prefixes.
- Insert chosen routes into IGP, since all routers must be able to forward packets to a destination IP.
- → (Optional) Announce newly created routes to the neighbouring As!

What are BGP attributes?

(LOCAL_PREF) 1. Local preference: The admin of the AS can say if they prefer a particular path.

(higher local preference = attribute value is greater = more preferable path)

(MED) 2. Multi-exit discriminator: If there are multiple Connections between two certain As', this shows the preference of using the wrent router.

(lower value = would prefer to receive messages on this router)

Advertised by the person sending the noute. Could set the MED as distance to the particular nouter.

(AS_PATH) 3. AS-path: This is just the list of AS numbers to the destination with that IP profix.

First AS which advertised

The destination As need not contain the destination IP due to say, supernetting.

4. Next hop: This is the IP address of the next router in the path (in the adjacent AS). This can be shared within a AS (using i-BGP).

Each BGP speaker chooses which As route to use among the many available for the same prefix. The rules to do so (in order of preference) are:

- 1. Use a route with the largest LOCAL_PREF.
- 2. Use a path with the shortest AS_PATH. (number of AS' on path)
- 3. Use a path with the lowest MED

(even across paths with distinct adjacent As')

This is called hot potato routing.

6. Use the path with the lowest ROUTER_ID among the BGP speakers which have sent the advertisement.

ROUTER_ID = highest IP address of all the router interfaces.
